Abstract

Forecasting future states of populations has taken on new urgency as the rate of climate change increases. Traditional plant population models have limited utility in this regard because they are based on detailed demographic data from small, localized plots. These models are difficult to scale up to spatial scales relevant to land managers that require such forecasts to make decisions. To overcome the data limitations of traditional population models, some have proposed population models based on population level, rather than individual level, data that is much easier to collect over broad spatial scales. Using such models violates a central assumption of ecology: individuals respond to weather, not populations to climate. Here, we test whether this assumption is important when forecasting climate change impacts on four perennial grass species in a semi-arid Montana grassland. We parameterized two population models, one based on individual level data with three vital rates and one on an aggregated version of the same data (percent cover), with climate covariates and compared their accuracy, precision, and sensitivity to climate. The individual level model was more accurate and precise than the aggregate level model when predicting out of sample observations. The aggregate level model made countervailing forecasts to 1% climate changes when compared to

¹Corresponding author: atredenn@gmail.com

the individual level model, indicating the aggregate level model produces incorrect forecasts. When comparing climate effects from both models, the aggregate level model tends to “miss” important climate effects from at least one vital rate for each species. It appears there is no short cut to forecasting climate change impacts on plant populations — detailed demographic data is essential. But, forecasts were very uncertain, so we advocate for a focus on new methods to collect demographic data more efficiently across environmental gradients in space and time.

Keywords: forecasting, climate change, grassland, integral projection model, population model

Introduction

Population models are important tools for predicting the impacts of environmental change on species. But reconciling the scales at which population models are parameterized and the scales at which environmental changes play out remains a challenge (Clark et al. 2010, 2012, Freckleton et al. 2011, Queenborough et al. 2011). The major hurdle is that most population models, at least for plant species, are built using data from small, localized plots because parameterizing traditional population models requires tracking the fates of individuals. These models are difficult to scale up from the micro to meso-scales because the fitted parameters do not fully represent the spatial variation present at scales beyond that at which the data are collected (Sæther et al. 2007). At the same time, most demographic data is collected over short time spans. For example, the most common study duration in the COMPADRE matrix population model database is 4 years and only a few exceed 10 years (Salguero-Gómez et al. 2015). The constrained spatio-temporal extent of most demographic datasets reflects the difficulty of collecting such data, but those constraints limit our ability to extrapolate population models. Thus, our ability to use population models to predict the consequences of climate change is limited when we rely on individual-level data.

Aggregate measures of individual plant performance, such as those typically collected as part

of large-scale census efforts, offer an alternative to detailed demographic data for modeling populations (Clark and Bjørnstad 2004, Freckleton et al. 2011). Such population-level data will never match the precision of individual-level data, but it is more feasible to attain a broad coverage sample when collecting coarse-scale data. This presents a difficult trade-off: on the one hand, individual-level data leads to more reliable models; on the other hand, population-level data leads to models that will produce less precise predictions but can be applied over greater spatial and temporal extents. An open question is how well models based on population-level data compare to models based on individual-level data.

To date, relatively few studies have tried to model populations based on data other than detailed individual-level data. An important exception is an effort by Taylor and Hastings (2004) to model the population growth rate of an invasive species to investigate the best strategies for invasion control. They used a “density-structured” model where the state variable is a discrete density state rather than a continuous density measure. Building on this work, Freckleton et al. (2011) showed that density-structured models compare well to continuous models in theory, and Queenborough et al. (2011) showed the application of such methods in a study on arable weeds. In particular, Queenborough et al. (2011) provide empirical evidence that density-structured models are capable of reproducing population dynamics, even if some precision is lost when compared to fully continuous models. Thus, population models based on coarse, population-level data show promise for producing ecological forecasts at landscape and regional scales (Queenborough et al. 2011). However, none of these models included environmental covariates.

Basing population models on aggregated individual-level data in a climate change context is hampered by the fact that it is individuals that respond to climate, not populations (Clark et al. 2012). This fact puts us in uneasy proximity to an “ecological fallacy” where one deduces inference on the individual from statistical inference on the group (Piantadosi et al. 1988). For example, individual plants may respond positively to precipitation but a negative trend is observed at the population level due to increased competition among plants

76 as they grow larger and consume more resources. Thus, it is important to ask the question:
77 Can aggregated data be used to detect climate signals of the same sign and magnitude as
78 individual-level data? If not, then building population models with climate covariates on
79 aggregated data will lead to incorrect forecasts.

80 Here, we test the assumption that statistical and population models based on aggregated
81 data can detect climate signals as well as models based on individual-level data. We use
82 a unique demographic dataset that tracks the fates of individual plants from four species
83 over 14 years to build single-species population models, since those are often used tools for
84 ecological forecasts and climate vulnerability assessments. We first fit population models
85 with interannual variation in vital rates explained, in part, by climate covariates. We then
86 perturb the climate covariates to test the sensitivities of species to climate change. By doing
87 these analyses using both individual and aggregated forms of the same data we can directly
88 compare the two types of models.

89 In general, we find that population models based on detailed demographic data are more
90 accurate and precise than models based on aggregated data. Both types of models are
91 able to detect climate signals, as evidenced by the sensitivity of simulated equilibrium plant
92 cover under a perturbed climate scenario. But the two types of models produce inconsistent
93 forecasts, in some cases producing completely opposing predictions. This leads us to conclude
94 that, at least for these species at this location, detailed demographic data is necessary to
95 detect the “right” climate signal. A worrying caveat to our work is that forecasts from both
96 models were very uncertain. It seems that even 14 years worth of demographic data is not
97 enough to produce meaningful forecasts when model uncertainty is explicitly considered.

Materials and Methods

Study site and data

Our demographic data comes from the Fort Keogh Livestock and Range Research Laboratory in eastern Montana’s northern mixed prairie near Miles City, Montana, USA (46° 19’ N, 105° 48’ W). The dataset is freely available on Ecological Archives² (Anderson et al. 2011) , and interested readers should refer to the metadata therein for a complete description. The site is about 800 m above sea level and mean annual precipitation (1878-2009) is 334 mm, with most annual precipitation falling from April through September. The site is grass dominated and, for the purposes of our study, we focus on the four most abundant graminoid species: *Bouteloua gracilis* (BOGR), *Hesperostipa comata* (HECO), *Pascopyrum smithii* (PASM), and *Poa secunda* (POSE) (Fig. 1).

From 1932 to 1945 individual plants were identified and mapped annually in 44 1-m² quadrats using a pantograph. The quadrats were distributed in six pastures, each assigned a grazing treatment of light (1.24 ha/animal unit month), moderate (0.92 ha/aum), and heavy (0.76 ha/aum) stocking rates (two pastures per treatment). In this analysis we account for potential differences among the grazing treatments, but do not focus on grazing×climate interactions. The annual maps of the quadrats were digitized and the fates of individual plants tracked and extracted using a computer program. Daily climate data, which we aggregated into climate variables of interest, are available for the duration of the data collection period (1932 - 1945) from the Miles City airport, Wiley Field, 9 km from the study site.

In this paper, we model populations based on two levels of data: individual and quadrat (Fig. 2). The individual data is the “raw” data. For the quadrat level we data we simply sum individual areal cover for each quadrat by species. This is equivalent to a perfect census of quadrat percent cover, so we do not need to consider measurement error. Based on these two datasets we can compare population models built using individual level data and aggregated

²<http://esapubs.org/archive/ecol/E092/143/>

123 quadrat level data.

124 All R code and data necessary to reproduce our analysis is archived on GitHub as release
125 1.0 (<http://github.com/atredennick/MicroMesoForecast/releases>). That stable release will
126 remain static as a record of this analysis, but subsequent versions may appear if we update
127 this work.

128 **Statistical models of vital rates**

129 At both levels of inference (individual and quadrat), the building blocks of our population
130 models are vital rate regressions. For individual level data we fit models for survival, growth,
131 and recruitment of new individuals for each species. At the quadrat level we fit a single
132 regression model for population growth. We describe the statistical models separately since
133 fitting the models required different approaches. All models contain five climate covariate that
134 we chose *a priori*: “water year” precipitation at $t-1$ (lagppt); fall through spring precipitation
135 at $t-1$ and $t-2$ (ppt1 and ppt2, respectively) and mean spring temperature at $t-1$ and $t-2$
136 (TmeanSpr1 and TmeanSpr2, respectively), where t is the observation year. We also include
137 interactions among same-year climate covariates (e.g., ppt1 \times TmeanSpr1) and climate \times
138 size interactions. Climate \times size interactions are for climate main effects only, that is we do
139 not include interactions among size and interacting climate effects.

140 We fit all models using a hierarchical Bayesian approach, which we describe in more detail
141 below. However, for each vital rate statistical model we also define the likelihood model we
142 use. For the likelihood models, \mathbf{Y} is always the relevant vector of observations (e.g., whether
143 a genet survived [1] or not [0] from year t to $t + 1$).

144 **Vital rate models at the individual level** We used logistic regression to model survival
145 probability (S) of genet i from species j in quadrat group Q from time t to $t + 1$:

$$\text{logit}(S_{ijQ,t}) = \gamma_{j,t}^S + \phi_{jQ}^S + \beta_{j,t}^S x_{ij,t} + \omega_j^S w_{ij,t} + \nu_j^S w_{ij,t} x_{ij,t} + \theta_{jk}^S C_{k,t} \quad (1)$$

$$Y_{ijQ,t}^S \sim \text{Bernoulli}(S_{ijQ,t}) \quad (2)$$

146 where $x_{ij,t}$ is the log of genet size, $\gamma_{j,t}^S$ is a year-specific intercept, $\beta_{j,t}^S$ is the year-specific slope
 147 parameter for size, ϕ_{jQ}^S is the random effect of quadrat group location, and θ_k^S is the fixed
 148 parameter for the effect of the k th climate covariate at time t ($C_{k,t}$). Note that the vector of
 149 climate covariates (\mathbf{C}) includes climate variable interactions and climate \times size interactions.
 150 We include density-dependence by estimating the effect of crowding on the focal individual
 151 by other individuals of the same species. ω is the effect of crowding and $w_{t,Q}$ is the crowding
 152 experienced by the focal individual at time t in quadrat group Q . We include a size \times crowding
 153 interaction effect (ν^S).

154 We modeled growth as Gaussian process describing genet size at time $t + 1$ as a function of
 155 size at t and climate covariates:

$$x_{ijQ,t+1} = \gamma_{j,t}^G + \phi_{jQ}^G + \beta_{j,t}^G x_{ij,t} + \omega_j^G w_{ij,t} + \nu_j^G w_{ij,t} x_{ij,t} + \theta_{jk}^G C_{k,t} \quad (3)$$

$$Y_{ijQ,t}^G \sim \text{Normal}(x_{ijQ,t+1}, \sigma_j) \quad (4)$$

156 where x is log genet size and all other parameters are as described for the survival regression.
 157 Our data allows us to track new recruits, but we cannot assign a specific parent to new genets.
 158 So, for recruitment, we work at the quadrat level and model the number of new individuals of
 159 species j in quadrat q recruiting at time $t + 1$ as a function of quadrat “effective cover” (A') in
 160 the previous year (t). Effective cover is a mixture of observed cover (A) in the focal quadrat
 161 (q) and the mean cover across the entire group (\bar{A}) of Q quadrats in which q is located:

$$A'_{jq,t} = p_j A_{jq,t} + (1 - p_j) \bar{A}_{jq,t} \quad (5)$$

where p is a mixing fraction between 0 and 1 that is estimated within the model.

We assume the number of individuals, Y^R , recruiting at time $t + 1$ follows a negative binomial distribution:

$$Y^R_{jq,t+1} \sim \text{NegBin}(\lambda_{jq,t+1}, \zeta) \quad (6)$$

where λ is the mean intensity and ζ is the size parameter. We define λ as:

$$\lambda_{jq,t+1} = A'_{jq,t} e^{(\gamma^R_{j,t} + \phi^R_{jq} + \theta^R_{jk} C_{k,t} + \omega^R \sqrt{A'_{q,t}})} \quad (7)$$

where A' is effective cover (cm^2) of species j in quadrat q and all other terms are as in the survival and growth regressions.

Population model at the quadrat level The statistical approach used to model vital rates using aggregated data depends on the type of data collected. In our case, and as is often the case with census data, we have percent cover data (which can easily be transformed to proportion data, of course). We first considered fitting three vital rate models analogous to those we fit at the individual level: one for probability of extirpation within a quadrat (analogous to survival), one for cover change within a quadrat (analogous to growth), and one for probability of colonization within a quadrat (analogous to recruitment). However, within-quadrat extirpation and colonization events were rare in our time series ($N = 9$ and $N = 10$, respectively across all species). Given the broad spatial distribution of the quadrats we are studying, it is safe to assume that these events are in fact rare enough to be ignored for our purposes. So we constrained our statistical modeling of vital rates at the population

level to change in percent cover within quadrats. For the remaining discussion of statistical modeling we refer to proportion data, which is simply percent data divided by 100.

An obvious choice for fitting a linear model to proportion data is beta regression because the support of the beta distribution is $[0,1]$, not including true zeros or ones. However, when we used fitted model parameters from a beta regression in a quadrat-based population model the simulated population tended toward 100% cover for all species. We therefore chose a more constrained modeling approach based on a truncated log-normal likelihood. The model for quadrat cover change (G) from time t to $t + 1$ is

$$x_{jq,t+1} = \gamma_{j,t}^G + \phi_{jQ}^G + \beta_{j,t}^G x_{jq,t} + \theta_{jk}^S C_{k,t} \quad (8)$$

$$Y_{jq,t+1}^G \sim \text{LogNormal}(x_{jq,t+1}, \tau j) \text{T}[0, 1] \quad (9)$$

where $x_{jq,t}$ is the log of species' j proportional cover in quadrat q at time t and all other parameters are as in the individual-level growth model (Eq. 3). Again, note that the climate covariate vector (\mathbf{C}) includes the climate \times cover interaction. The log normal likelihood includes a truncation ($\text{T}[0,1]$) to ensure that predicted values do not exceed 100% cover.

Model fitting

Our Bayesian approach to fitting the vital rate models required choosing appropriate priors for unknown parameters and deciding which, if any, of those priors should be hierarchical. We decided to fit models where all terms were fit by species. Within a species, we fit yearly size effects and yearly intercepts hierarchically where year-specific coefficients were drawn from global distributions representing the mean size effect and intercept. We used flat, uninformative priors for all unknown parameters (Appendix X).

All of our analyses (model fitting and simulating) were conducted in R (R Core Development

Team 2013). We used the ‘No-U-Turn’ MCMC sampler in Stan (Stan Development Team 2014a) to estimate the posterior distributions of model parameters using the package ‘rstan’ (Stan Development Team 2014b). We obtained posterior distributions for all model parameters from three parallel MCMC chains run for 1,000 iterations after discarding an initial 1,000 iterations. We recognize such short MCMC chains may surprise those more familiar with other MCMC samplers (i.e. JAGS or WinBUGS), but the Stan sampler is exceptionally efficient, which reduces the number of iterations needed to achieve convergence. We assessed convergence visually and made sure scale reduction factors for all parameters were less than 1.01. For the purposes of including parameter uncertainty in our population models, we saved the final 1,000 iterations from each of the three MCMC chains for all parameters to be used as randomly drawn values during population simulation. This step alleviates the need to reduce model parameters by model selection since sampling from the full parameter space in the MCMC ensures that if a parameter broadly overlaps zero, on average the effect in the population models will also be near zero.

Population models

With the posterior distribution of the vital rate statistical models in hand, it is straightforward to simulate the population models. We used an Integral Projection Model (IPM) to model populations based on individual level data and an quadrat based version of an individually-based model (Quadrat-Based Model, QBM) to model populations based on quadrat level data. We describe each in turn.

Integral projection model We use an environmentally stochastic IPM (Rees and Ellner 2009) that includes the random year effects and the climate covariates from the vital rate statistical models. But note that we can, and do for some simulations, ignore the random year effects so that only the climate effects can drive interannual variation. Our IPM follows the specification of Chu and Adler (2015) where the population of species j is a density function

224 $n(u_j, t)$ giving the density of sized- u genets at time t . Genet size is on the natural log scale,
 225 so that $n(u_j, t)du$ is the number of genets whose area (on the arithmetic scale) is between e^{u_j}
 226 and e^{u_j+du} . So, the density function for any size v at time $t + 1$ is

$$n(v_j, t + 1) = \int_{L_j}^{U_j} k_j(v_j, u_j, \bar{\mathbf{w}}_j(u_j))n(u_j, t) \quad (10)$$

227 where $k_j(v_j, u_j, \bar{\mathbf{w}}_j)$ is the population kernel that describes all possible transitions from size u
 228 to v and $\bar{\mathbf{w}}_j$ is a vector of estimates of average crowding experienced from all other species
 229 by a genet of size u_j and species j . The integral is evaluated over all possible sizes between
 230 predefined lower (L) and upper (U) size limits that extend beyond the range of observed
 231 genet sizes.

232 The population kernel is defined as the joint contributions of survival (S), growth (G), and
 233 recruitment (R):

$$k_j(v_j, u_j, \bar{\mathbf{w}}_j) = S_j(u_j, \bar{\mathbf{w}}_j(u_j))G_j(v_j, u_j, \bar{\mathbf{w}}_j(u_j)) + R_j(v_j, u_j, \bar{\mathbf{w}}_j), \quad (11)$$

234 which, said plainly, means we are calculating growth (G) for individuals that survive (S)
 235 from time t to $t+1$ and adding in newly recruited (R) individuals of an average sized
 236 one-year-old genet for the focal species. Our stastical model for recruitment (R , described
 237 above) returns the number of new recruit produced per quadrat. Following previous work
 238 (Adler et al. 2012, Chu and Adler 2015), we assume that fecundity increases linearly with
 239 size ($R_j(v_j, u_j, \bar{\mathbf{w}}_j) = e^{u_j} R_j(v_j, \bar{\mathbf{w}}_j)$) to incorporate the recruitment function in the spatially-
 240 implicit IPM.

241 We used random draws from the final 1,000 iterations from each of three MCMC chains to
 242 introduce stochasticity into our population models. At each time step, we randomly selected
 243 climate covariates from one of the 14 observed years. Then, we drew the full parameter
 244 set (climate effects and density-dependence fixed effects) from a randomly selected MCMC

iteration. Using this approach, rather than simply using coefficient point estimates, ensures that relatively unimportant climate covariates (those that broadly overlap 0) have little effect on the simulation results. Since our focus was on the contribution of climate covariates to population states, we set the random year effects and the random group effects to zero.

Quad-based model Our quad-based model (QBM) perfectly mirrors its statistical description (Eq. 8-9). We use the same approach for drawing parameter values as described for the IPM.

Model validation

To test each model’s ability to forecast the population state we made out of sample predictions using leave-one-year-out cross validation. For both levels of modeling, we fit the vital rate models using observations from all years except one, and then used those fitted parameters in the population models to perform a one-step-ahead forecast for the year whose observations were withheld from model fitting. Within each observation year, several quadrats are sampled. So we made predictions for each observed quadrat in the focal year initialized with cover the previous year. Since we were making quadrat specific predictions we incorporated the group effect on the intercept for both models. We repeated this procedure for all 13 observation years, making 100 one-step-ahead forecasts for each quadrat-year combination with parameter uncertainty included via randomdraw from the MCMC chain as described above. Random year effects were set to zero since year effects cannot be assigned to unobserved years.

This model validation allowed us to compare accuracy and precision of the two modeling approaches (individual-level versus population-level). We first calculated the median predicted cover across the 100 simulations for each quadrat-year and then calculated the absolute error as the difference between the observed cover for a given quadrat-year and the median prediction. To arrive at mean absolute error (MAE), we then averaged the absolute error within each species across the quadrat-year specific errors. We use MAE as our measure of

accuracy. To measure precision we calculated the distance between the upper and lower 90th quantiles of the 100 predictions and averaged this value over quadrat-years for each species.

Testing sensitivity to climate covariates

Our main goal in this paper is to see if models based on aggregate level data are as sensitive to climate as models based on individual level data. So, with our fitted and validated models in hand, we ran simulations for each model type (IPM and QBM) under four climate perturbation scenarios: (1) observed climate, (2) precipitation increased by 1%, (3) temperature increased by 1%, and (4) precipitation and temperature increased by 1%. We ran the simulations for 2,500 time steps, enough to estimate equilibrium cover after discarding an initial 500 time steps as burn-in. Each simulation was run under two parameter scenarios: (1) using mean parameter estimates and (2) using randomly drawn parameters from the MCMC chain. We use (1) to detect the overall sensitivity of equilibrium cover to climate, and we use (2) to show the impact of model uncertainty on forecast precision.

As an effort to identify potential discrepancies between IPM and QBM forecasts, we also ran simulations designed to quantify the sensitivities of individual and combined vital rates to climate for the IPM. Specifically, we ran simulations for the above climate scenarios, but applied the perturbed climate covariates to survival, growth, and recruitment vital rates individually and in pairwise combinations. This allows us to isolate the vital rate(s) most sensitive to climate. For this analysis, we used mean parameter estimates to reduce the sources of uncertainty in the sensitivity estimates.

Results

Comparison of forecast models

The IPM had significantly lower overall error (MAE, mean absolute error) for three species (*B. gracilis*, *H. comata*, *P. smithii*; Table 1). In no case did the QBM significantly outperform the IPM (Table 1). The IPM was consistently more precise than the QBM, with lower distances between the 90% quantiles across all species (Table 1). In general the IPM outperformed the QBM because it had (1) lower MAE for three of the four species, (2) statistically similar MAE for the one other species, and (3) considerably more precise forecasts for all species.

Sensitivity of models to climate

Equilibrium cover from both models was sensitive to climate (Fig. 3a-d). The IPM projected percent changes in equilibrium cover from -3 - 8% for *B. gracilis*, -4 - 3% for *H. comata*, -15 - 9% for *P. smithii*, and -17 - 53% for *P. secunda*. The QBM projected opposite and greater percent changes in equilibrium cover for *B. gracilis* (-63 - 30%) and *H. comata* (-50 - -18%; Fig. 3a-b). For *P. smithii*, the QBM projected opposite changes in equilibrium cover than the IPM, but of similar magnitude (-5 - 6%; Fig. 3c). *P. secunda* was the only species that the IPM and QBM made projections of the same sign and somewhat similar magnitude (Fig. 3d).

The response of a population to climate change is a result of the aggregate effects of climate on individual vital rates. Since the IPM approach relies on vital rate regressions, we were able to quantify the sensitivity of each vital rate in isolation and in pairwise combinations. Species showed similar trends (Fig. 3e-h). Growth was the most sensitive vital rate for all species, showing a negative response to increased precipitation, and stronger positive response to increased temperature, and a mostly positive response when both climate factors are increased (Fig. 3e-h). *B. gracilis* survival rates were sensitive to temperature, resulting in an

increase in plant cover under increased temperature (Fig. 3e). In isolation, recruitment and survival were insensitive to climate factors for *H. comata* (Fig. 3f). Survival and recruitment of *P. smithii* were both sensitive, negatively, to temperature and precipitation (Fig. 3g). *P. secunda* equilibrium cover was sensitive to the climate effects on survival and recruitment, showing a negative effect on both vital rates for increased precipitation, but a strong positive effect on survival with increased temperature (Fig. 3h). The climate impact of recruitment on equilibrium cover was negative for precipitation and temperature increases (Fig. 3h). Forecasts based on 1% climate changes were extremely uncertain when we considered model error and parameter uncertainty (Fig. 4). As expected based on model validation (Table 1), QBM projections were more uncertain than IPM projections for all species except *P. smithii* (Fig. 4).

Discussion

Perhaps the greatest challenge for ecology in the 21st century is to forecast the impacts of environmental change (Clark et al. 2001, Petchey et al. 2015). To do so requires sophisticated modeling approaches that fully account for uncertainty and variability in the ecological process and associated parameters (Luo et al. 2011). This requires large amounts of data collected over large spatio-temporal extents. State-of-the-science modeling techniques cannot overcome data limitations. Such is the case for many population models.

As a potential remedy to the “data dearth” problem, Queenborough et al. (2011) and Freckleton et al. (2011), building on work by Taylor and Hastings (2004), advocate a “density-structured” modeling approach. Such models do not require individual level demographic data and can adequately describe population dynamics (Queenborough et al. 2011). The results from density-structured models are not as precise as those from traditional population models, but the loss in precision is traded off with a gain in data. The study by Queenborough et al. (2011) included data from 500 fields (4 hectares each) in 49 farms, all collected by two

people in 6 weeks. This is far more data from a far greater spatial extent than possible if measuring individual plant demography (in a world of limited time and money, at least). The appeal of density-structured approaches is clear.

However, at their core, density-structured models rely on individual level data aggregated to a population level metric (e.g., density classes or percent cover). This creates a potential problem if such models are to be used in a climate change context because individuals respond to climate, not populations (Clark et al. 2012). Are models based on population level metrics as sensitive to climate as models based on individual level metrics? Do these two types of models produce consistent forecasts? Do we need detailed demographic data to forecast the impacts of climate change? These are the questions we sought to answer here.

The IPM and QBM produced inconsistent forecasts

Using individual and aggregated forms of the same dataset, we were able to directly compare a traditional demographic modeling approach to a population model based on aggregated data. Our quad-based model (QBM) is based on percent cover data and so is in the spirit of density-structured models. In terms of each model's forecasting ability, the IPM outperformed the QBM (Table 1). This is unsurprising since we expected to lose some precision at the aggregated level. However, the underwhelming performance of the QBM could call into the question forecasts that differ from the IPM.

Indeed, when we perturbed climate factors the QBM made forecasts completely contradictory to those of the IPM for three of our four study species (Fig. 3a-d). In a perfect world, the QBM would have made forecasts of at least the same direction as the IPM. If that had been the case we could conclude that aggregate level models could prove useful for forecasting climate change impacts on populations. Unfortunately, this was not the case.

Given the superior ability of the IPM to predict out of sample observations (Table 1), we have no choice but to conclude it is the superior model. Following that logic, we can only

assume that, at least contingent on the data in hand, the IPM is producing the correct forecasts to climate perturbations. The QBM failed to match IPM forecasts, implying that detailed demographic data may be necessary to accurately detect climate signals that are ultimately important at the population level. This result further confirms related work on the importance of individual variability on population level responses to exogenous drivers (Clark et al. 2011a, 2011b, 2012, Galván et al. 2014).

The role of vital rate climate dependence

We can think of two reasons why the IPM outperformed the QBM. First, the quadrat level data has a much reduced sample size compared to the individual level data. In an ideal world we would have compared the IPM and QBM using data collected over the same amount of person hours, not just the same number of quadrats. Then the sample size of the quadrat level data would be much greater and carry more statistical power. To address this limitation in our work we fit the QBM statistical model (Eq. 8-9) with different numbers of quadrats to see the effect of sample size on the precision of climate effect estimates. It appears that including additional quadrats leads to rapidly diminishing returns in terms of parameter precision (Fig. 5). Thus, while sample size surely plays some role, we do not think it is the main driver of the difference between the IPM and QBM.

The second reason the IPM could have outperformed the QBM is that the population level model is in fact missing important climate effects that act on individual vital rates, rather than population growth. Our intuition was that species with strong climate-dependence on vital rates not well resolved at the aggregate level would result in different forecasts from the two models. For example, survival is very size dependent: smaller individuals have a higher probability of death (Chu and Adler 2014). At the same time, a single small individual contributes relatively little to percent cover estimates at the plot scale. So, if survival of individuals was positively impacted by temperature increases, for example, we would expect

to detect this signal in the individual level data but not in the aggregate level data. To see if this is the case we can regress climate effects from each vital rate statistical model at the individual level against the same climate effects from the QBM statistical model (Fig. 6).

In general, the QBM climate effects are most correlated with climate effects from the growth model at the individual level (Fig. 6). In no case does the QBM statistical model have strong correlations across all three vital rates (Fig. 6). Thus, for each species the QBM is “missing” climate signals associated with at least one vital rate. This has large impacts on predictions of long term population dynamics, as seen in our equilibrium simulations (Fig. 3a-d).

These results lead us to conclude that detailed demographic data is necessary to forecast climate change impacts on plant populations. This is unwelcome news since this data is difficult to collect and the models built on such data are of little use to land managers that make decisions at scales beyond that of traditional population models (Queenborough et al. 2011). While density-structured approaches may fail when climate covariates are considered, there are other alternatives. For example, (???) use Forest Inventory and Analysis (FIA) data to parameterize a population model with multiple vital rates and climate dependence. Another example are distributed efforts like PlantPopNet (<http://plantago.plantpopnet.com>) that will allow researchers to estimate variation around climate responses for widespread species. Lastly, we foresee new approaches on the horizon that leverage photo/video of plots and advanced object recognition algorithms to streamline plant mapping and digitizing efforts.

Forecasting the future, and the future of forecasting

Our goal was not make any explicit forecast for the future state of these populations based on predicted climate change. But our results highlight the state of affairs in ecology when it comes to forecasting the impacts of climate change. The analysis we conducted here could be considered, with some exceptions of course, at the forefront of ecological forecasting in terms

414 of the statistical approach employed (hierarchical Bayesian), the type of population model
415 we used (stochastic IPM with parameter uncertainty), and the amount of data we had at our
416 disposal (14 years of individual-level data). Yet, model predictions proved so uncertain that
417 any forecast, when bounded with model and parameter uncertainty, would be at best not
418 useful and at worst meaningless. How might we improve on this state of affairs?

419 First, forecasts could be improved by matching the spatial scale of predictor variables with
420 the spatial scale of observations. One of the major limitations of the models we fit here is that
421 the climate data are at a much larger scale than the plot and individual level observations of
422 plant cover and size. Climate covariates only vary by year, with no spatial variability within
423 years. Thus, even if we fit models to individual level data, we are missing the key interaction
424 point between weather and individual plants (Clark et al. 2011b).

425 Second, accurately detecting climate signals will take even longer time series. Recent
426 theoretical work on detecting climate signals in noisy data suggests that even advanced
427 approaches to parameter fitting like LASSO, functional linear models (splines), and random
428 forest require 20-25 year time series (Teller et al., in review). Alternatively, as we suggest
429 above, Teller et al. (in review) also find that matching the scale of the response and predictors
430 improves estimate precision.

431 Third, ecologists as a community need to get serious about reporting uncertainty. There is a
432 strong culture around explicitly considering model uncertainty, but parameter uncertainty
433 is often ignored. In some cases this is because the easiest statistical methods do not make
434 propagating parameter uncertainty easy. Even using Bayesian approaches that allow straight-
435 forward integration of model fitting and forecasting (Hobbs and Hooten 2015) is not simple
436 when using modeling approaches like integral projection models that separate the model
437 fitting and simulation stages (Rees and Ellner 2009). However, as we have done here, it is
438 still possible to include parameter uncertainty by drawing parameter values from MCMC
439 iterations, taking care to draw all parameters from the same chain and iteration to account

for their correlations. Only by being honest about our forecasts can we begin to produce better ones.

Conclusions

This work is not a critique of density-structured population models. In some cases and for certain species, population models based on aggregated data may prove useful and unbiased. However, our work here is the first comparison, to our knowledge, of population models based on individual and aggregated data in a climate change context. Our results confirm theoretical arguments (Clark et al. 2011b) and empirical evidence (Clark et al. 2011a, 2012) that individual responses are critical to predicting species' responses to climate change. Thus, forecasts from aggregate level models should be viewed with caution and should never be unaccompanied by uncertainty. Given the importance of demographic data and its current difficulty to collect, we advocate for research on modern methods to collect demographic data more efficiently across environmental gradients in space and time. For example, recent advances in object recognition algorithms (Liu et al. 2014) provide new opportunities to speed up data collection and digital processing.

Our results also offer a cautionary tale because uncertainty around forecasts was large for both model types. Which leads us to our most pessimistic conclusion: even with 14 years of detailed demographic data and sophisticated modeling techniques we failed to produce forecasts with any level of acceptable uncertainty. In our view, uncertainty of climate change related forecasts can be reduced by (1) longer time series and (2) climate covariates that match the scale of inference (e.g., plot rather than landscape level climate/weather metrics). Still, given the poor performance of the quad-based model, it seems there is no short cut to producing accurate and precise population forecasts. Do we need detailed demographic data to forecast the impacts of climate change on populations? Probably.

Acknowledgments

This work was funded by the National Science Foundation through a Postdoctoral Research Fellowship in Biology to ATT (DBI-1400370) and a CAREER award to PBA (DEB-1054040). We thank the original mappers of the permanent quadrats in Montana and the digitizers in the Adler lab, without whom this work would not have been possible. Informal conversations with Stephen Ellner, Giles Hooker, Robin Snyder, and a series of meetings among the Adler and Weecology labs at USU sharpened our thinking. Compute, storage and other resources from the Division of Research Computing in the Office of Research and Graduate Studies at Utah State University are gratefully acknowledged.

Table 1: Accuracy (mean absolute error, MAE) and precision (90% Distance) of out of sample predictions. Forecasts were made without random year effects; only climate covariates could explain year-to-year variation. 90% Distance refers to the average distance between the upper and lower 90th percentiles of the 100 predicted values for each quadrat-year combination.

Species	Model	MAE	90% Distance	Mean Obs. Cover
BOGR	IPM	12.18	38.52	9.43
BOGR	QBM	19.66	56.50	9.26
HECO	IPM	1.22	6.47	1.15
HECO	QBM	12.35	41.11	1.18
PASM	IPM	0.19	1.65	0.42
PASM	QBM	0.55	7.78	0.42
POSE	IPM	1.37	7.64	1.25
POSE	QBM	1.79	40.59	1.27

474 *NOTES:* The IPM MAE is significantly lower at $\alpha = 0.05$ for *B. gracilis* ($P = 0.0012$), *H.*
475 *comata* ($P = 4.0586 \times 10^{-8}$), and *P. smithii* ($P = 3.183 \times 10^{-5}$). MAEs are statistically
476 similar between models for *P. secunda* ($P = 0.0922$). P values are highly sensitive to sample
477 size, so not entirely appropriate in simulation exercises where we control the samples size.
478 But, for our purposes they serve as relatively unbiased comparison metrics.

Figure 1: Time series of average percent cover over all quadrats for our four focal species: *Bouteloua gracilis* (BOGR), *Hesperostipa comata* (HECO), *Pascopyrum smithii* (PASM), and *Poa secunda* (POSE). Light grey lines show trajectories of individual quadrats. Note the different y-axis scales across panels.

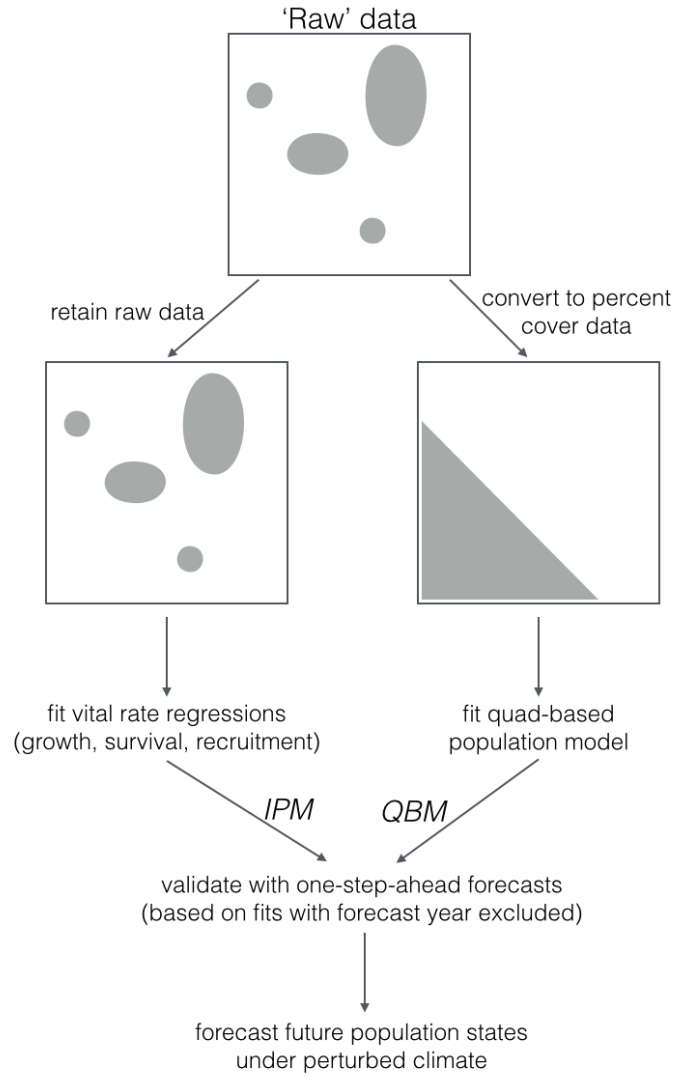

Figure 2: Work flow of the data aggregation, model fitting, and population simulating.

Figure 3: Proportional change in species' mean cover caused by a 1% increase in observed precipitation (+ppt), temperature (+temp), or both (+ppt&temp) as predicted by the individual-based IPM and the aggregate-based QBM using mean parameter values. Top panels show the mean predicted proportional change in cover. Lower panels show the sensitivity of equilibrium cover simulated from the IPM to each climate scenario applied to individual and combined vital rates. For example, the points associated with G show the median cover from IPM simulations where a climate perturbation is applied only to the growth regression climate covariates. These simulations also use mean parameter values for clarity.

Figure 4: Equilibrium cover and 90% quantiles around the mean prediction when model error and parameter uncertainty are propagated through the simulation phase. Climate simulations are as in Figure 3.

Figure 5: Effect of quadrat sample size on the precision (standard deviation) of main climate effect estimates in the QBM. Increasing the number of quadrats results in diminishing returns in terms of parameter certainty. Light dashed lines show individual climate effects at five quadrat sample sizes. Thick dark lines are inverse gaussian fits showing the mean effect of increasing quadrat sample size on parameter precision.

Figure 6: Correlations between QBM and IPM estimates of climate effects. We ignore sizeXclimate interactions since these are not directly comparable across model types. The QBM does not have multiple vital rates, so its values are repeated across panels within each species.
